Abstract. On a research flight on 10 July 2008, the German research aircraft Falcon sampled an air mass with unusually high carbon monoxide (CO), peroxyacetyl nitrate (PAN) and water vapour (H\textsubscript{2}O) mixing ratios in the Arctic lowermost stratosphere. The air mass was encountered twice at an altitude of 11.3 km, ∼800 m above the dynamical tropopause. In-situ measurements of ozone, NO, and NO\textsubscript{y} indicate that this layer was a mixed air mass containing both air from the troposphere and stratosphere. Backward trajectory and Lagrangian particle dispersion model analysis suggest that the Falcon sampled the top of a polluted air mass originating from the coastal regions of East Asia. The anthropogenic pollution plume experienced strong up-lift in a warm conveyor belt (WCB) located over the Russian east-coast. Subsequently the Asian air mass was transported across the North Pole into the sampling area, elevating the local tropopause by up to ∼3 km. Mixing with surrounding Arctic stratospheric air most likely took place during the horizontal transport when the tropospheric streamer was stretched into long and narrow filaments. The mechanism illustrated in this study possibly presents an important pathway to transport pollution into the polar tropopause region.

1 Introduction

Although located thousands of kilometres from major industrial regions, the Arctic troposphere is polluted by the import of anthropogenic emissions (e.g. Law and Stohl, 2007). Pollution enters the Arctic mainly during winter and spring by long-range transport (LRT) from the industrial regions of North America, Europe and Asia. Models even suggest a year-round import from the northern mid-latitudes, with source regions varying with season (Eckhardt et al., 2003; Klonecki et al., 2003; Stohl, 2006; Shindell et al., 2008). However, large uncertainties remain regarding the transport pathways, and the relative contributions of different source regions. One objective of the POLARCAT project (http://www.polarcat.no) was to combine both aircraft and satellite observations with models in order to study the role of long-range poleward transport of trace gases and aerosols on climate change in the Arctic.

Depending on the source region, anthropogenic emissions may reach the Arctic through several transport patterns. According to Stohl (2006), pollution from Asia and North America enters the Arctic mainly at higher altitudes, as relatively warm and moist mid-latitude air masses ascend over colder, denser arctic air masses; followed by descent within the Arctic or transport back to lower latitudes. The necessary up-lift of industrial emissions from the boundary layer to the middle and upper troposphere efficiently takes place within so-called warm conveyor belts (WCBs) (e.g. Stohl...
and Trickl, 1999; Stohl, 2001; Cooper et al., 2002, 2004; Stohl et al., 2003). WCBs are defined as strongly ascending moist airstreams in extratropical cyclones that, on short time-scales of 1 or 2 days, rise from the boundary layer to the upper troposphere (e.g. Wernli and Davies, 1997; Eckhardt et al., 2004). The ascent is accompanied by an increase of potential temperature due to latent heat release from water vapour condensation, cloud formation, and a loss of moisture by precipitation. WCBs frequently entrain polluted air masses from the industrialized eastern seaboard of North America and Asia (Stohl et al., 2001; Wernli and Bourqui, 2002), with Asian WCBs experiencing stronger ascent (Wild and Akimoto, 2001; Stohl et al., 2002).

The export of Asian pollution is of great concern, since anthropogenic emissions in Asia have increased rapidly in recent years (e.g. Akimoto et al., 2003; Richter et al., 2005; Zhang et al., 2009). Measurements performed in the source region of Asian WCBs show extremely high mixing ratios of pollutants. In North East China, CO values of up to 1185 nmol mol\(^{-1}\) were measured in the warm sector ahead of a cold front, originating from the North China Plain (Ding et al., 2009). For similar meteorological conditions within developing WCBs, the CO mixing ratios are found to be about a factor of five higher in China as compared to the US (Dickerson et al., 2007). After up-lift within the WCB, the polluted Asian air masses are transported globally, predominantly by the westerly winds. Numerous airborne observations of Asian plumes have been conducted above the North American continent (e.g. Jaffe et al., 1999, 2003; Jaeglé et al., 2003; Hudman et al., 2004), and even above Europe (Stohl et al., 2007; Fiedler et al., 2009).

During LRT, the chemical composition of the polluted air masses is altered through chemical transformation (Jacob et al., 2003; Hudman et al., 2004; Singh et al., 2009) and mixing with surrounding air (Trickl et al., 2003; Stohl et al., 2007). Mixing processes may take place in the vicinity of fronts (Esler et al., 2003) or in the WCB outflow region (Cooper et al., 2002; Mari et al., 2004). Mixing with stratospheric air may also occur in the mid- and upper troposphere (Parrish et al., 2000; Brioude et al., 2007; Stohl et al., 2007). In the extra-tropical UTLS (upper troposphere/lowermost stratosphere) region, large-scale stirring and inter-mingling of air masses leads to the formation of a mixing layer, and can be quantified using tracer relationships (Fischer et al., 2000; Zahn et al., 2000; Hoor et al., 2002, 2004; Pan et al., 2004, 2007; Kunz et al., 2009). Exchange across the extratropical tropopause plays an important role for the trace gas composition in the lowermost stratosphere, affecting both local chemistry and the radiative budget. It is therefore notable that Lagrangian transport climatologies show a potential for WCB trajectories to reach the tropopause region (Stohl, 2001; Wernli and Bourqui, 2002). A few percent of these trajectories even enter the lowermost stratosphere, not only within active WCBs, but also a few days after the WCBs decay (Eckhardt et al., 2004). Since some of the WCBs reach polar latitudes, it is conceivable that anthropogenic pollution can be transported into the polar lowermost stratosphere within a few days after emission. This transport pathway has not yet been verified by observations, however, measurements show in general relatively high CO mixing ratios of 100 nmol mol\(^{-1}\) and more in the polar lowermost stratosphere (Cooper et al., 2005; Tilmes et al., 2010).

In the present paper we demonstrate that Asian pollution can reach the Arctic tropopause region within a few days after emission. To the best of our knowledge, our study presents the first in-situ observation of a distinct Asian pollution plume recently transported into the Arctic lowermost stratosphere. The anthropogenic emissions were up-lifted within a warm conveyor belt over eastern Russia, transported across the Arctic and probed by the Falcon above northern Greenland, where it was already mixed with stratospheric air. The aim of this paper is to present in-situ trace gas observations, to analyze the origin of the encountered air mass, and to discuss its lifting process and transport history.

The present paper is organized as follows: Sect. 2 describes the methods used in the analysis. A detailed description of the case study is given in Sect. 3, beginning with a presentation of the meteorological situation at the time of our measurements (Sect. 3.1) and a discussion of the in-situ observations (Sect. 3.2). Subsequently, the source region of the encountered air mass is identified by using a Lagrangian particle dispersion model and a backward trajectory model (Sect. 3.3). The analysis of the meteorological situation in the source region (Sect. 3.4) as well as during transport to Greenland (Sect. 3.5) is followed by a discussion of tracer correlations (Sect. 3.6.1) and mixing processes that have occurred during the cross-polar transport (Sect. 3.6.2). Section 4 provides the summary and conclusions.

2 Data and model descriptions

2.1 Chemical measurements

The data presented in this paper were measured on 10 July 2008, on a flight with the DLR (Deutsches Zentrum für Luft- und Raumfahrt) Falcon research aircraft above northern Greenland. The flight was conducted within the framework of the GRACE campaign (Greenland Aerosol and Chemistry Experiment), a sub-project of the POLARCAT (Polar Study using Aircraft, Remote Sensing, Surface Measurements and Models, of Climate, Chemistry, Aerosols, and Transport) initiative. GRACE was conducted in summer 2008 (30 June–18 July) and aimed to study the influence of both boreal forest fire and anthropogenic emissions on the composition of the troposphere and lowermost stratosphere in the summer-time Arctic. During GRACE, the Falcon was based in Kangerlussuak, Greenland (67.01° N, 50.7° W). A total of 16 local flights were performed, covering latitudes from 57° N to 81.5° N, longitudes from 66° W to 16° E and altitudes up
The FLEXPART model was used in order to attribute anthropogenic and biomass burning pollution sources to the in-situ observations. FLEXPART is a Lagrangian particle dispersion model (Stohl et al., 2005, and references herein). For this study, it was driven with meteorological analyses from the European Centre for Medium-Range Weather Forecasting (ECMWF) with a 5° × 5° resolution. FLEXPART includes a sub-grid scale convective transport scheme. Stochastic fluctuations are obtained by solving Langevin equations (Stohl and Thomson, 1999) and are superimposed on the grid-scale winds to represent transport by turbulent eddies. For CO, NO\textsubscript{2}, and SO\textsubscript{2}, the EDGAR (Emissions Database for Global Atmospheric Research) version 3.2 emission inventory for the year 2000 (fast track) on a 1° × 1° grid was used outside North America and Europe. Over Europe, the EMEP (European Monitoring and Evaluation Programme) emission inventory for the year 2005 with a resolution of 0.5° × 0.5° was used and over most of North America, the inventory of Frost et al. (2006) for the year 1999. While such a merged emission data set contains methodological inconsistencies with regard to how the emissions have been derived, for the purpose of our study the higher resolution and more recent information offered by the regional inventories compared to the EDGAR data set more than outweigh that disadvantage. Previous experience with the 1995 EDGAR inventory has shown that Asian CO emissions are underestimated (probably by a factor of 2 or more), while American CO emissions may be overestimated. For the input of biomass burning emissions, hot spot locations are obtained daily from measurements made with MODIS onboard the Aqua and Terra satellites and are compared to a land-use inventory with 1-km resolution. The emissions are estimated assuming an area burned of 180 ha per fire detection. They depend on a parameterization based on biomass available for burning, the fraction actually burned, and emission factors, all dependent on land-use. Fire emissions were only distributed within the lowest 150 m of the boundary layer and fires burned for 24 h (Stohl et al., 2007). All pollution tracers underlie passive transport without involving removal processes. After a life-time of 20 days, the tracers are removed under the assumption that they become incorporated into the so-called atmospheric background (Sodemann et al., 2011).

The present study also uses FLEXPART backward simulations. These were started along the flight track every time the Falcon moved by 0.15 degrees in either longitude or latitude, or whenever the altitude changed by 10 hPa. For each release 60 000 particles were followed backward in time for 20 days. The model output of such backward simulations consists of fields of emission sensitivities which can be multiplied with emission fields to yield maps of source contributions for passive tracers (Stohl et al., 2003). When spatially integrated, tracer mixing ratios are obtained, allowing to construct tracer time series along the flight path. We consider CO, NO\textsubscript{2} and SO\textsubscript{2} separately for both anthropogenic and biomass burning pollution from Asia, North America and Europe. Further information is given by the fraction of particles remaining in the stratosphere during the last 20 days. For this, troposphere and stratosphere are distinguished based on a threshold of 2 PVU (potential vorticity units).

2.3 LAGRANTO trajectories

The Lagrangian Analysis Tool (LAGRANTO; Wernli and Davies, 1997) was used to investigate the origin of the observed air masses over Greenland. The calculations are based on three-dimensional wind fields of 6-hourly ECMWF operational analyses at a 1° horizontal grid resolution. Several variables characterizing the physical state of the air parcels including potential temperature, specific humidity and potential vorticity were traced along the trajectory paths.

In this case we used two different set-ups of LAGRANTO to calculate forward and backward trajectories. 8-day backward trajectories were started close to the observation time on 10 July, 18:00 UTC. These were initialized at a constant pressure level within a box centered around the region where the pollution was sampled (see later Sect. 3.3.2). Additionally, a method to diagnose warm conveyor belt trajectories was used (Wernli and Davies, 1997), by selecting only boundary layer air parcels that ascend poleward to the upper troposphere and lowermost stratosphere over a short time period (see Sect. 3.4).

2.4 Composite satellite images

The Antarctic Meteorological Research Center (AMRC) provides Arctic composite satellite images every three hours, creating a total of eight images per day (Lazzara and
Fig. 1. (a) Flight path of the DLR Falcon on 10 July 2008 between ~14:30 UTC and 18:30 UTC (red line) superimposed on ECMWF analysis data at 18:00 UTC of pressure (colour shaded, hPa) at the 2 PVU (dynamical tropopause) surface and geopotential height at 300 hPa (black lines, m). (b) Flight path, colour-coded by ΔCO above altitude-dependent background values as derived from all GRACE data. Areas with ΔCO < 10 nmol mol\(^{-1}\) are shown in dark blue. North of approx. 77.5° N, an air mass with enhanced CO mixing ratios was entered by the Falcon, both on the outbound and return leg at a constant flight level (11.3 km). The thickness of the line indicates the altitude (larger markers represent higher altitudes). For more details see text.

3 Results and discussion

3.1 Meteorological situation at upper levels

The weather situation close to the time of observation (10 July 2008, 18:00 UTC) is presented in Fig. 1a using 300 hPa geopotential height (black isolines) and pressure altitude \(p_{2PVU}\) of the dynamical tropopause, defined as the 2 potential vorticity units (PVU) surface (colour-coded). The red line gives the Falcon flight path. The geopotential height shows a large-scale trough over north-eastern Canada with a discrete low over the Davis Strait. The entire trough region is characterized by a low dynamical tropopause (equivalent to high values of \(p_{2PVU}\), up to ~400 hPa within the closed contour line of the low). On its leading edge, the low has southerly flow at 300 hPa (see geopotential isolines) and the dynamical tropopause is situated at ~300 hPa. Above northern Greenland, north of a nearly east-west oriented narrow filament with a lower tropopause (\(p_{2PVU} > 400\) hPa), the dynamical tropopause is at higher levels (\(p_{2PVU} > 230\) hPa). The associated air mass is located in the diffuent exit region of a jet. At this time the jet was located right over the pole, as shown by the widening spacing of geopotential isolines from the North Pole towards the most northern part of the 10 July flight.

3.2 In-situ observations

On the flight on 10 July 2008, CO values up to 138 nmol mol\(^{-1}\) were observed at 11.3 km altitude, whereas during GRACE typical CO mixing ratios at this altitude were ~40 to 50 nmol mol\(^{-1}\). Figure 1b shows the...
Fig. 2. Time series of measured trace gases for the GRACE flight on 10 July 2008, between 15:30 and 17:00 UTC. (a) O$_3$ in blue and CO in red, (b) NO$_y$ in green and NO in purple, (c) PAN in orange and CO$_2$ in light blue, (d) H$_2$O in light green and potential temperature $\Theta$ in grey. Missing data correspond to internal calibration periods. (e) Flight altitude (latitude is colour-coded) and potential vorticity in black, as interpolated from the ECMWF analysis at 18:00 UTC. The flight segment discussed in the present study is highlighted in light red (“MR”), whereas the remaining data at this flight altitude are denoted by “LMS” (lowermost stratosphere). See text for more details.

Falcon flight-path, for illustration purposes it is colour-coded by the measured ΔCO above the altitude-dependent CO background (see colour-scale on the top right). The CO background here is defined as the 30th percentile of all POLARCAT-GRACE measurements, calculated separately for altitude bins of 1 km. ΔCO values of $<$10 nmol mol$^{-1}$ are shown in dark blue. The marker size represents the flight altitude (larger markers indicate higher altitudes).

After take-off in Kangerlussuaq, the Falcon climbed up to 11.3 km altitude while flying north (up to point P1), and then $\sim$60 km to the east (towards point P2). On the way back to the south, the Falcon descended at $\sim$75.5° N to 7.9 km before landing again in Kangerlussuaq. The layer with enhanced CO was traversed twice, both on the outbound and the return leg, right before point P1 and after point P2. The maximum horizontal separation is 60 km (P1 to P2). Comparison with Fig. 1a shows that the layer with enhanced CO agrees well with the region of elevated tropopause, as indicated by the lower atmospheric pressure at the 2 PVU surface.

Figure 2 presents the time-series for several trace gases for a part of the flight between 15:30 and 17:00 UTC (see time markers in Fig. 1b). It shows CO and O$_3$ (a), NO and NO$_y$ (b) together with PAN and CO$_2$ (c). Also given are the potential temperature $\Theta$ and the water vapour mixing ratio (d). The time resolution is 1 s, except for PAN, which is reported every 2 s. Panel e shows the flight altitude (colour-coded by the latitude of the Falcon), and potential vorticity as interpolated from the ECMWF analysis fields. The two way points
P1 and P2 are marked as vertical lines (see Fig. 1b). The red shaded area in Fig. 2 highlights the flight segment with enhanced CO. In the following we will refer to this segment as mixing region “MR”. The remaining data sampled at the same altitude, i.e. further south of “MR”, are denoted by “LMS” (lowermost stratosphere).

When the Falcon entered the “MR”, CO increased from about 40 nmol mol$^{-1}$ up to $\sim 140$ nmol mol$^{-1}$ over a time span of $\sim 7$ min (corresponding to $\sim 80$ km). The Falcon then observed a sharp decrease in CO down to $\sim 80$ nmol mol$^{-1}$, and a region of moderate CO values of 100 nmol mol$^{-1}$ ($\sim 65$ km). At the most northern point, CO did not completely drop to mixing ratio values observed further south in the lowermost stratosphere (“LMS”), which indicates that the aircraft possibly did not traverse the entire mixing region. The time-series of the trace gases inside the “MR” is nearly symmetric due to its twofold sampling. The CO enhancement in the “MR” was accompanied by an increase of the tropospheric pollutant PAN (up to $\sim 330$ pmol mol$^{-1}$ compared to $\sim 40$ pmol mol$^{-1}$ in the “LMS”), and of water vapour ($\sim 80$ µmol mol$^{-1}$ compared to $\sim 20$ µmol mol$^{-1}$ in the “LMS”). The trace gases with generally higher values in the stratosphere than in the unpolluted regions of the troposphere (i.e. O$_3$, NO and NO$_2$) showed smaller mixing ratios within the “MR” of down to 100 nmol mol$^{-1}$, 30 pmol mol$^{-1}$ and 900 pmol mol$^{-1}$, respectively. The anticorrelation of the different trace gases indicates that the Falcon sampled an air mass of both tropospheric and stratospheric origin. The interpretation of the chemically inert greenhouse gas CO$_2$ (atmospheric lifetime of $\sim 100$ yr) however is more complicated, due to underlying temporal and spatial variations (see Sect. 3.6.1). In some parts of the “MR” some smaller scale filaments are observed (indicated by black arrows).

Thermodynamic parameters also vary within the “MR”. Potential temperature $\Theta$ and potential vorticity both decrease, pointing to a less stable stratification in the “MR”. Potential vorticity during this part of the flight had a minimum value of $\sim 5$ PVU, and the minimum vertical distance between flight altitude and the 2 PVU tropopause was $\sim 800$ m (see Sect. 3.5).

3.3 Identification of source region

3.3.1 FLEXPART backward simulations

The results of the FLEXPART backward runs initialised along the flight track are shown in Fig. 3b. To allow an easier comparison, the in-situ O$_3$ and CO time-series are repeated in Fig. 3a. Generally, the structure of the “MR” is very well captured by the FLEXPART model. The blue line in panel b gives the fraction of air with a stratospheric origin which decreases inside the “MR” to a minimum of $\sim 50\%$. The red pattern in Fig. 3b represents the Asian excess-CO, indicating that the tropospheric part of the encountered air mass was polluted by anthropogenic emissions of Asian origin. According to the FLEXPART simulations, contributions from industrial pollution sources from other continents or from biomass burning are negligible.

The CO source contribution plot for 16:11 UTC (CO maximum) is given in Fig. 3c. This plot represents the product between the anthropogenic emission flux (taken from the emission inventories) and the footprint emission sensitivity. The latter is proportional to the residence time of the particles over a unit area in the lowest 100 m (Stohl et al., 2005). The CO source contribution plot shows that the pollution mainly originates from the North China Plain, one of the most densely populated regions in China, with some minor contributions from the North East China Plain and Korea. According to the model, the pollution was emitted approximately 6–10 days before our measurements (not shown).

3.3.2 LAGRANTO backward trajectories

In order to analyze the transport history of the sampled “MR” and “LMS” air masses, we calculated an ensemble of 8 day LAGRANTO backward trajectories. The results are illustrated in Fig. 4. A total of 242 trajectories were released in an area from $-60^\circ$ E to $40^\circ$ E and $75^\circ$ N to $82^\circ$ N (see black rectangle in Fig. 4a) at 217 hPa on 10 July, 18:00 UTC. The colour-code gives the latitude of the starting position and the black line within the rectangle shows the Falcon flight track. Figure 4b to d shows the temporal evolution of meteorological parameters along the trajectories (pressure, humidity, potential temperature).

We can mainly distinguish between two different air mass origins in this area. Trajectories in the southern part of the box were transported from northern North America towards Greenland, remaining above 300 hPa. These trajectories characterize the pathway for the sampled “LMS” air masses. The cyclonic curvature indicates transport within the large scale trough described in Sect. 3.1 (see also Fig. 1a). Trajectories in the northern part of the box were traced back across the North Pole to Siberia/Russia. Some parcels moved directly over the pole (yellow), while others were influenced by the upper level high that caused an anti-cyclonic rotation (blue and green).

The time series of pressure along the trajectories shows that independent of their origin, most of the parcels were transported at high altitudes above 300 hPa (see Fig. 4b). Their PV values were predominantly larger than 2 PVU which points to stratospheric transport (not shown). Only a small number of the trajectories experienced a strong vertical displacement. Remarkably, three of these parcels (thick grey lines in Fig. 4) originate from the boundary layer in the industrialized coastal regions of China and Korea, where they had the possibility to take up anthropogenic pollution. This is in good agreement with the results of the FLEXPART analysis (see Sect. 3.3.1). The subsequent fast and strong ascent from ground level to the upper troposphere is accompanied by a strong loss of humidity and an increase of the potential
Fig. 3. (a) Time series of in-situ CO (red), O$_3$ (blue), and pressure at flight altitude (black) for the same time period shown in Fig. 2. (b) Results of the FLEXPART backward analysis: the blue line gives the stratospheric fraction along the flight path. The red pattern represents the FLEXPART excess-CO originating from Asian anthropogenic pollution. (c) CO source contribution plot for 16:11 UTC (maximum CO concentration at 11.3 km altitude) with colour-scaling on the right.

3.4 Meteorological situation in the source region

To study the ascent process within the warm conveyor belt, 48 h LAGRANTO forward trajectories were initiated on every grid point in a box over Asia (90°E to 150°E, 30°N to 75°N and between 1000 hPa and 750 hPa), as indicated in Fig. 5. Within the 8-day period from 2 July 2008, 18:00 UTC to 10 July 2008, 18:00 UTC, every 6 h a new set of trajectory calculations was initialised, and calculated for a 48 h interval. From all trajectories, only those showing a pressure decrease greater than 600 hPa within 24 h were selected, and considered as warm conveyor belt trajectories. The computation of all selected 48 h WCB trajectories was then completed over temperature as a result of latent heat release. The strong uplift of the trajectories took place over eastern Russia between 5 July, 12:00 UTC (−126 h) and 6 July, 18:00 UTC (−96 h), as indicated by the grey dots in Fig. 4. According to FLEXPART, the pollution was emitted between ~1−4 July, i.e. ~6−10 days before our measurements. The polluted air mass was transported for a few days at low levels towards the northeast before it was exported from the boundary layer. The characteristics of strong and poleward ascent in combination with latent heat release suggests up-lift by a WCB, which is further investigated in the following section.
Fig. 4. LAGRANTO 8-day backward trajectories released on 10 July, 18:00 UTC, every 40 km inside the black box at 217 hPa. The box was centred around the encountered “MR”. The flight track of the 10 July flight is shown as black line. The colour-code of the trajectories represents the starting latitude of the trajectories. Green trajectories belong approx. to the region of the “MR”. Panel (a) gives a polar view of the pathways. Two sections are shown at a larger scale on the top: The release box (left) as well as the ascent over eastern Asia (right). The three panels (b), (c) and (d) show the evolution of pressure, specific humidity, and potential temperature along the trajectories. The time on the x-axis is relative to 10 July, 18:00 UTC. The trajectories highlighted as thick grey lines experience a strong ascent over eastern Asia. Two time marks (gray dots) at −126 h (5 July, 12:00 UTC) and at −96 h (6 July, 18:00 UTC) indicate the location of this lifting process.

3.5 Cross-polar transport and vertical structure of the polluted Asian air mass

The transport of the Asian pollution plume across the pole is illustrated in Fig. 6. The left panel shows satellite image composites for 4 points in time, covering the time
Fig. 5. Synoptic evolution from ECMWF analyses and position of WCB parcels at (a) 5 July, 00:00 UTC; (b) 5 July, 12:00 UTC; (c) 6 July, 00:00 UTC; (d) 6 July, 12:00 UTC, (e) 7 July, 00:00 UTC, and (f) 7 July, 12:00 UTC. Thick black lines show geopotential height at 300 hPa (80 gpm interval). Thin grey lines illustrate the mean sea level pressure (4 hPa interval). The black polygon marks the region in which the trajectories were initialized (for details of the calculation method see Sect. 3.4). The colour-coded dots show location and pressure of the parcels at the respective time step.

period after the up-lift within the WCB (6 July 2008) to the day of our measurements above northern Greenland (10 July 2008). As described in Sect. 2.4, the cold upper-level cloud tops are illustrated by yellow and red colours. The white contour lines represent the FLEXPART Asian anthropogenic CO tracer, but only for the column above 9 km. For the same points in time, the right panel shows maps of FLEXPART Asian CO tracer plotted on 340 K isentropes. The red line indicates where the 325 K isentropes crosses the 2 PVU surface, giving the approximate position of the jet stream. The red crosses indicate the location of a subset (every 8th) of the pole-crossing WCB forward trajectories (see Sect. 3.4).
Fig. 6. Cross-polar transport of the Asian pollution. (a) and (b) 6 July, 18:00 UTC, (c) and (d) 7 July, 18:00 UTC, (e) and (f) 6 July, 09:00 UTC, (g) and (h) 10 July, 15:00 UTC. Left panels: Satellite composite images with colour-coded cloud top temperatures (see colour-scaling at the left). White contour lines show FLEXPART Asian CO for the column above 9 km. Black asterisks indicate locations of weather stations in the region of the WCB (marked by the fronts in panel (a)). The Falcon flight path is superimposed in panel (g). Right panels: FLEXPART Asian CO tracer plotted on the 340 K isentrope (see-colour-scaling on the right). Red line gives the location of the dynamical tropopause (2 PVU) at the 325 K surface. The red crosses indicate the position of the WCB forward trajectories. The black line shows the location of the cross section presented in Fig. 8. For more details see text.
According to our trajectory analysis, the WCB ascent ahead of the cold front took place over Eastern Russia approximately between 5 July, 18:00 UTC and 7 July, 00:00 UTC. On 6 July, 18:00 UTC, our WCB trajectories reached the upper troposphere, coinciding with an area of enhanced CO tracer columns above 9 km of 100 g m$^{-2}$ ahead of the cold front (Fig. 6a). Soundings from four weather stations (black asterisks in Fig. 6a) indicate that the minimum cloud top temperatures of $\sim$240–223 K within the WCB correspond to a maximum altitude of $\sim$11 km. CO is used as a passive tracer with a life-time of 20 days in the FLEXPART model runs, therefore other CO pollution “remnants” north of Kamchatka/east of North Siberia are also visible in the upper troposphere, possibly from earlier lifting events. However, the polluted air mass lifted within the studied mid-latitude cyclone reached high potential temperatures of 340 K, shown in a comparison with Fig. 6b. As indicated by the red line, a tropospheric streamer had already begun to intrude into the Arctic, ahead of an upper level trough. In the following hours and days, a low pressure system formed, deepened and moved further to the north (indicated with “L” in Fig. 6a, c, e). The polluted Asian air mass therefore was advected towards the North Pole (Fig. 6c, 7 July, 18:00 UTC). Whereas most of the Asian CO tracer was advected eastwards, some of the Asian CO was embedded in the streamer (Fig. 6d). A comparison of Fig. 6c and d shows that the region of enhanced FLEXPART tracer is accompanied partly by upper level clouds. During its journey, the polluted streamer was elongated and deformed (Fig. 6c and f, 9 July, 06:00 UTC).

Finally, a portion of the polluted streamer reached northern Greenland, where it was sampled by the Falcon on 10 July (Fig. 6g and h, 10 July, 18:00 UTC). Figure 6h illustrates the good agreement with our in-situ data, showing that the polluted streamer was located almost perpendicular to our flight track, and was not completely traversed (see also Sect. 3.6). During the cross-polar transport, the tropospheric streamer elevated the polar tropopause substantially (see also Fig. 1a).

Figure 7 illustrates the temporal evolution of the vertical temperature structure during the advection of the streamer. Temperature profiles from soundings before, during and after the passage of the polluted streamer are presented exemplary for Eureka, Canada ($79.98^\circ$ N, $85.95^\circ$ W), and show a tropopause height variation of $\sim$2.5 km. Due to the mid-latitude origin of the polluted Asian air mass, the temperature at a fixed level in the middle to upper troposphere is $\sim 5$ to 10 K higher inside the Asian air mass (red solid lines) in comparison to the Arctic air mass (blue dotted lines), whereas the tropopause temperature is up to $\sim$7 K lower. The region above $\sim$13 km is less affected by the dynamics of the tropospheric streamer. During the passage of the Asian air mass the tropopause is sharper than before and after. The maximum thermal tropopause is $\sim 11.5$ km (11 July, 00:00 UTC), which is slightly above our flight altitude (11.3 km). Note however the considerable temporal and spatial difference between the soundings and our in-situ measurements. An analysis of ECMWF temperature profiles indicates that e.g. at the time of the observation, the thermal tropopause was $\sim$500 m lower in the sampled part of the streamer than above Eureka.

Figure 8 shows a vertical cross section of the FLEXPART Asian excess-CO tracer around the time of the flight (see black line in Fig. 6h). Also given are isentropes (black lines), the 2 PVU dynamical tropopause (thick black line), as obtained from the ECMWF analysis data, as well as isotherms (blue lines). The red crosses indicate the position of the WCB forward trajectories. Only WCB trajectory points located within 200 km of the Falcon flight path are shown (within 16:30 h $\pm$ 3 h). Their abundance close to or above the 2 PVU tropopause reflects the strong selection criteria of the WCB forward analysis ($\Delta 600$ hPa within 24 h).

According to the FLEXPART model simulation, the Falcon probed the topmost part of an Asian pollution plume with a vertical extension of several km. The Asian excess-CO shows a maximum of $\sim 90$ to 100 nmol mol$^{-1}$ at about 9 km just below the dynamic tropopause, at the edges of the tropospheric streamer. A part of the pollution reached the lowermost stratosphere, as indicated both by the 2 PVU tropopause and the closer spacing between the isentropes. According to ECMWF analysis, the plume was sampled $\sim 800$ m above the dynamic tropopause and $\sim 400$ m above the thermal tropopause, respectively. The Falcon nearly reached the centre of the streamer which is indicated by the region of the
3.6 Discussion

3.6.1 Tracer-tracer correlations

As shown in Sects. 3.2 and 3.3, both in-situ measurements and the FLEXPART analysis indicate that we probed an air mass of both stratospheric and tropospheric origin. In this section we discuss the chemical properties of the sampled air mass using correlations between different trace gases. Tracer-tracer relationships are a common tool to investigate mixing, chemical and/or transport processes in the tropopause region (Hoor et al., 2002, 2004; Pan et al., 2004, 2007; Kunz et al., 2009).

The red crosses in Fig. 9a–d represent the 10 July data observed inside the “MR”. For comparison, the 10 July “LMS” data are also shown (black circles). The grey open circles represent all other GRACE data, as obtained from all 16 local flights. For the following discussion it is worth noting that although the GRACE measurement area was far from pollution sources, the sampled data do not represent summertime CO background values. In the free troposphere values were biased towards higher CO mixing ratios (as well as PAN and NO$_x$). The Arctic mid-troposphere frequently was impacted by long-range transport of aged but CO-enriched pollution plumes, originating mainly in the boreal forest regions in Canada and Siberia (Singh et al., 2010; Schmale et al., 2011). Therefore, the median CO value between 4 to 9 km during GRACE was $\sim$140 nmol mol$^{-1}$, whereas in the undisturbed troposphere of the northern mid- and high latitudes, CO mixing ratios typically range from approx. 80 to 120 nmol mol$^{-1}$ (Emmons et al., 2000; Fischer et al., 2006).

Figure 9a shows an O$_3$-CO scatter plot. O$_3$-CO correlations help to diagnose STE (Stratosphere-Troposphere Exchange) because both O$_3$ and CO show distinct vertical gradients in the vicinity of the extratropical tropopause, with higher O$_3$ in the stratosphere and higher CO in the troposphere, respectively. Ozone is mainly produced in the tropical stratosphere and has a life-time of approx. 1 yr in the lowermost stratosphere (Solomon et al., 1985). In the troposphere, O$_3$ values are highly variable due to in-situ photochemical production/destruction, dry deposition and import of stratospheric air. The main CO source in the background troposphere and the stratosphere is the oxidation of CH$_4$. Other tropospheric CO sources are incomplete combustion processes from human activities or biomass burning, which makes CO an excellent pollution tracer. Its major sink is the reaction with OH radicals, which results in generally lower CO background values in the summer troposphere compared to winter, and for the same reason in the tropics compared to the middle and polar latitudes (Novelli et al., 1992, 2003).
The “MR” data in the O₃-CO scatter plot in Fig. 9a can be represented by a regression line, a so-called mixing line, which is formed by irreversible mixing of air parcels of both stratospheric and tropospheric origin. The slope of such a mixing line in a tracer-tracer space is dependent on the trace gas mixing ratios of the initial air masses (e.g. Hoor et al., 2002). The tropospheric character is found to be highest in the centre of the “MR” (see also Fig. 1b). Here, the CO mixing ratio of \( \sim 138 \text{nmol mol}^{-1} \) suggests predominantly tropospheric origin whereas the ozone mixing ratio of \( \sim 100 \text{nmol mol}^{-1} \) is already at the upper limit of typical tropospheric values. Although photochemical in-situ production in strongly polluted air masses may cause such high ozone values, this might indicate that also this part of the streamer had already mixed with ozone-rich stratospheric air masses. At the edges of the “MR”, the entrainment of O₃-rich, stratospheric air is more prominent.

A comparison of the “MR” data with the remaining GRACE data shows that the “MR” CO values in the tropopause region and above (i.e. O₃ > 100 nmol mol⁻¹) are biased towards higher CO mixing ratios. This suggests that a CO-enriched air mass was mixed into the lowermost stratosphere, which confirms the FLEXPART model results. If mixing and not chemical transformation is the dominant process, the extrapolation of the regression slope to an assigned tropospheric value of O₃ gives an indication of the CO concentration of the “tropospheric end-member” (Hintsa et al., 1999; Hermann et al., 2000; Hoor et al., 2002). If we assume an upper tropospheric ozone mixing ratio of 70 (±30) nmol mol⁻¹, we can calculate an initial CO mixing ratio of 143 (±10) nmol mol⁻¹, as indicated by the dark red marker in Fig. 9a. It has to be pointed out that the tropospheric end-member represents only the tropospheric air mass just before it mixed with the stratospheric air. The WCB inflow regions however can be quite large (Wernli, 1997; Eckhardt et al., 2004), which means that the anthropogenic emissions certainly have been diluted with less polluted air already in the troposphere.

Figure 9b shows the relation between O₃ and H₂O. Water vapour mixing ratios show an even stronger gradient across the extratropical tropopause than O₃ and CO. The entry of H₂O into the stratosphere occurs primarily in the tropics, however in the extratropics a moist mixing layer in the lowermost stratosphere is an indicator of troposphere-to-stratosphere transport occurring at higher latitudes (e.g. Krebsbach et al., 2006). The moisture in the extratropical tropopause region is largely a function of the temperature at the cold point tropopause, but depends also on the relative
strength of the different transport paths. Water vapour has a long chemical life-time in the tropopause region, but it is not conserved if condensation followed by precipitation occurs.

Apparently the “MR” data are divided into two regimes A and B, which are separated approximately at O$_3$ and H$_2$O values of 280 nmol mol$^{-1}$ and 65 µmol mol$^{-1}$, respectively. The data in group A form a mixing line which can be extrapolated towards assigned tropospheric ozone values of 70 (±30) nmol mol$^{-1}$. The corresponding H$_2$O end-member of 144 (±10) µmol mol$^{-1}$ is indicated by the dark red marker in Fig. 9b. It gives an approximate value of the H$_2$O content of the air mass after it was up-lifted within the WCB, but before it mixed with drier air from the stratosphere. This water vapour mixing ratio is in the same range of values obtained from the backward trajectory calculations, suggesting that after the strong loss of moisture that is characteristic of WCB lifting events, H$_2$O mixing ratios of ∼0.06–0.1 g kg$^{-1}$ (corresponding to ∼96–160 µmol mol$^{-1}$) remain within the air mass (see grey trajectories in Fig. 4c, at ∼72 h). The high water vapour mixing ratio in the WCB region raises the question whether this transport pathway may lead to an enhanced moistening of the extratropical lowermost stratosphere, though an upscaling cannot be done from our single event study. This might have implications for the temperature and chemistry of the UTLS, as water vapour plays an important role in the radiation budget and is a primary source of HO$_x$ radicals (e.g. Fueglistaler et al., 2009; Kunz et al., 2009). The data of group B correspond to the centre of the “MR”, and clearly deviate from the regression line. Obviously water vapour was removed in this part of the air mass due to phase transition followed by sedimentation. This assumption is supported by the occurrence of the high-level clouds in some parts of the streamer, visible in the satellite images (e.g. Fig. 6c, e).

A CO$_2$-CO scatter plot is presented in Fig. 9c. Apart from an increasing trend during the last decades due to industrialization, CO$_2$ has seasonal, diurnal, and spatial variations. It is, for example, depleted during summertime in the lower troposphere by plant assimilation. This seasonal cycle, typically ±1 µmol mol$^{-1}$ in the southern Hemisphere up to ∼15 µmol mol$^{-1}$ in the northern boreal forest zone (Wigley and Schimel, 2000), is propagated into the lowermost stratosphere (e.g. Sawa et al., 2008; Boenisch et al., 2009). This is also reflected in the GRACE data, the observed CO$_2$ mixing ratios were on average ∼2 µmol mol$^{-1}$ lower in the troposphere than in the lowermost stratosphere: Median CO$_2$ for O$_3$<100 nmol mol$^{-1}$ was 381.4±0.4 µmol mol$^{-1}$ compared to 383.3±0.2 µmol mol$^{-1}$ for O$_3$ values >100 nmol mol$^{-1}$.

The “MR” data show a linear dependence between CO$_2$ and CO. Positive correlations between CO$_2$ and CO are typically observed for combustion sources, and the ΔCO$_2$/ΔCO enhancement ratio may provide information about the combustion efficiency. However, in this case the CO$_2$/CO slope is driven by the mixing processes between the tropospheric and the stratospheric air masses. Due to the absence of well-defined (tropospheric) background values not affected by pollution, the enhancement ratio ΔCO$_2$/ΔCO ratio is difficult to quantify. Nevertheless, the CO$_2$/CO ratio of the air sample having the highest fraction of tropospheric air (i.e. CO$_2$ ~ 385 µmol mol$^{-1}$ at CO ~ 140 nmol mol$^{-1}$) clearly stands out from the remaining GRACE data, which were affected mainly by imported biomass burning plumes. This comparatively high CO$_2$/CO ratio might be the combined result of two effects: Combustion efficiencies of industrial processes (e.g. of power plants) are much higher than those of forest fires, leading to initial CO$_2$/CO slopes of up to a magnitude higher in anthropogenic plumes compared to biomass burning pollution (Andreae and Merlet, 2001; Suntharalingam et al., 2004). Additionally, the CO$_2$ “background” might differ for these two different source regions. In densely populated areas like the North China Plain, respiratory CO$_2$ of urban residents as well as agricultural soils and livestock is part of the anthropogenic plume and increases the CO$_2$/CO ratio (Wang et al., 2010). On the contrary, CO$_2$ plant uptake in boreal regions during summer leads to a decrease of this ratio.

Figure 9d shows a NO$_3$-O$_3$ scatter plot. In the stratosphere, NO$_3$ is primarily composed of HNO$_3$ and NO$_x$, produced mainly in the tropics by the photolysis of N$_2$O followed by oxidation (Murphy et al., 1993). The NO$_x$ composition in the troposphere might differ considerably depending on sources/sinks, as well as region and altitude. As obvious in the GRACE data, correlations between NO$_3$ and O$_3$ are typically steeper in the troposphere than in the stratosphere (Murphy et al., 1993). The NO$_3$ values of the “MR” data do not stand out from the remaining GRACE measurements, suggesting that although the air mass was influenced by anthropogenic pollution and hence, by emission of NO$_x$, the main part of the emitted NO$_3$ did not reach high altitudes. This is in agreement with earlier studies which show that the export of NO$_3$ from the boundary layer is not very efficient (Stohl et al., 2003; Koike et al., 2003; Nowak et al., 2004), mainly because of the removal of water-soluble HNO$_3$ due to precipitation processes. Furthermore, the polluted air mass resided a few days in the boundary layer before it ascended within the WCB (see Sect. 3.3.2), which means that also dry deposition at the surface might have played a role.

Beyond HNO$_3$, PAN is the most dominant NO$_3$ species found in aged pollution (Koike et al., 2003; Nowak et al., 2004; Singh et al., 2010). PAN is a product of hydrocarbon-NO$_x$ chemistry and has long life-times in the mid- and upper troposphere (Talukdar et al., 1995). In the region of weakest stratospheric influence (i.e. at highest CO), a maximum PAN/NO$_3$ ratio of ∼0.3 is observed. This ratio is rather low, PAN/NO$_3$ ratios of up to ∼0.85 have been measured in other CO plumes during GRACE, and ratios of e.g. ∼0.65 in aged Asian pollution (Nowak et al., 2004). PAN is not affected by dry deposition and survives the up-lift in a mid-latitude cyclone (e.g. Miyazaki et al., 2003), but it has a life-time of only a few hours at the warm temperatures prevalent in the...
boundary layer (Talukdar et al., 1995). The low PAN content therefore is very likely the result of thermal decomposition during the low-level transport in the first days after emission. PAN may recycle back especially during night-time. However, in the humid boundary layer the released NO$_2$ is efficiently oxidized to HNO$_3$ (e.g. Bradshaw et al., 2000), especially during summer at these latitudes. As discussed earlier, most of the HNO$_3$ in the WCB was presumably removed by wet deposition.

Compared to the “MR” slopes, the regression lines of the “LMS” data are much steeper for all correlations. The CO values of up to 50 nmol mol$^{-1}$ are well above the stratospheric equilibrium value of 12 to 15 nmol mol$^{-1}$ (Flocke et al., 1999) which suggests also for these air masses recent influence from the troposphere (e.g. Hoor et al., 2002, 2004; Tilmes et al., 2010), but to a lesser extent. Compared to the tropospheric air mass mixed into the “MR”, the tropospheric air in the “LMS” case contained much less H$_2$O, PAN and CO, but slightly higher NO$_y$ and much higher CO$_2$.

### 3.6.2 Mixing of Asian pollution with Arctic stratospheric air

As discussed before, the polluted Asian air mass had already mixed with stratospheric air when it was sampled by the Falcon, although some interleaved filaments were still observed (see Sect. 3.2). An interesting question is of course, when and why did the tropospheric and stratospheric air masses mix? As mentioned in Sect. 3.4, most air parcels reached the 2 PVU level during the up-lift within the WCB, or later during the ascent at the leading edge of the upper level trough. Certainly mixing processes took place between the ascending Asian pollution and the lowermost stratospheric air located above, especially at the top of the lifted air mass.

However, we suggest that the main part of the troposphere-to-stratosphere (TST) exchange evident in our data happened during the period of cross-polar transport at elevated levels: As mentioned in Sect. 3.5, the polar tropopause was vertically displaced during the passage of the tropospheric streamer. Temperature soundings from several weather stations (Eureka, Alert and Danmarkshavn, see red crosses in Fig. 6g) show an up-lift of the thermal tropopause of $\sim$2.5 to 3 km. This in turn implies that the polluted air mass was above $\sim$9 to 10 km embedded by stratospheric air from the Arctic, while it was advected across the pole. As discussed in Sect. 3.5, the tropospheric streamer was elongated and stretched into long and narrow filaments during its journey. Therefore the most likely scenario is that horizontal shear induced turbulent mixing and thus, mass exchange across the air mass boundaries took place. As suggested by the “MR” in-situ data, O$_3$-rich and CO-poor stratospheric air masses were entrained at the boundaries of the polluted filament. Another strong indication for more recent TST exchange is the linear mixing line which is observed in the O$_3$-CO scatter plot (Fig. 9a). The quasi-ideal linear shape indicates mixing between two air masses having well-defined tracer “end-members”. Mixing processes at an earlier stage during the WCB uplift would rather be evident in deviations from this ideal mixing line (due to subsequent mixing and/or chemical processes). Finally, our assumption is also supported by the forward trajectory calculation started in the source region. As addressed in Sect. 3.4, the trajectories reach PV > 2 PVU within the WCB ascent or shortly later. However, PV further increases along the forward trajectories travelling across the pole, finally reaching values between 3 and 10 PVU above Greenland. This additional gain in PV (and Theta) reflects, at least to some extent, further entrainment of PV-rich, warmer air from the stratosphere during the cross-polar transport.

However, we have to keep in mind that our data only represent a “snap-shot” in the temporal evolution of 3-dimensional mixing events, documenting the mixing stage only at one location and one point in time. The role of radiation (cooling/heating) is not discussed here, but may be relevant due to the existence of clouds, or at least humidity differences.

### 4 Summary and conclusions

During the research flight on 10 July 2008 an air mass containing unusually high CO, PAN, and H$_2$O mixing ratios of 138 nmol mol$^{-1}$, 330 pmol mol$^{-1}$ and 81 µmol mol$^{-1}$ was sampled in the Arctic tropopause region at 11.3 km, $\sim$800 m above the dynamical tropopause (2 PVU). In-situ tracer correlations and FLEXPART backward simulations show that we probed the topmost part of an air mass with recent tropospheric origin, containing anthropogenic pollution from East Asia mixed with O$_3$-rich stratospheric air. As supported by a detailed trajectory analysis, the Asian pollution was uplifted within a WCB connected to a low pressure system over Northern Russia. The analysis also showed that 92% of the pole-crossing WCB trajectories reached the dynamical tropopause, mainly within the WCB ascent or shortly later. A part of the Asian pollution was embedded in a tropospheric streamer, which was advected across the pole. During its journey, the top of the polluted air mass was surrounded by Arctic stratospheric air. TST exchange most likely took place along the sides of the plume, when the tropospheric streamer was stretched into long and narrow filaments. Forward trajectory calculations initialized at the location of our observation show a steady increase in PV during the following 5 days (from 5.1 PVU to 9.4 PVU on average) suggesting that the pollution has been completely mixed into the lowermost stratosphere.

Correlation analyses show that the polluted tropospheric air mass was enriched mainly in CO, CO$_2$ and H$_2$O before it was mixed into the stratosphere, whereas PAN and NO$_y$ have been efficiently removed before and during the up-lift within the WCB. While the wet removal of HNO$_3$ is a regular occurrence in the transport pathway discussed herein,
PAN generally has the potential to reach the tropopause region within WCB ascents, if the up-lift is not preceded by multi-day-transport in the warm boundary layer. The transport of pollution across the Pole was associated with an Arctic low-pressure system. Such cyclone events in the proximity of the North Pole are regular phenomena of the polar circulation, especially during summer (Serreze and Barret, 2007; Orsolini and Sorteberg, 2009), though the described cross-polar transport period was unusually strong (Sodemann et al., 2011).

Our study presents the first in-situ measurement of WCB-lifted Asian pollution being stirred and finally irreversibly mixed into the polar lowermost stratosphere. In the context of our observations the question arises: is this transport process a common scenario that brings pollution to the polar lowermost stratosphere, as already suggested by climatological studies (Stohl, 2001; Wernli and Bourqui, 2002)? Our measurements are possibly linked to other observations: Dessler (2009) showed that even at high latitudes of 75–80° N, cloud tops are found ~20 % of the time above the summertime tropopause. Since convection is not very frequent in these regions, WCBs may possibly be one reason for these observations. Furthermore, the lowermost stratosphere north of the jet stream contains a wide range of CO mixing ratios (Cooper et al., 2005), and in polar regions CO exceeds 100 nmol mol⁻¹ 25 % of the time in the 1 km thick layer above the summertime tropopause (Tilmes et al., 2010), indicating frequent entrainment of polluted air masses. The influence on local stratospheric chemistry is not clear: mixing of O₃-rich stratospheric with H₂O-rich tropospheric air may result in enhanced OH mixing ratios and hence, a higher oxidation capacity (Esler et al., 2001). The influence of anthropogenic pollutants such as CO, CO₂, and SO₂ however is difficult to predict.

Further research is required to (a) better assess the relevance of polluted WCBs on the Arctic UTLS region and (b) understand possible consequences on the chemical and radiative budget, especially in the context of rising Asian emissions and changing climate.
